

The Service (in SQL?)

The core of the Person Data Service could probably be built in SQL but does not have to be.

So, first is a big picture “Technology Agnostic” view of what will happen:

However we implement this, I would like to see a “data driven” model for identifying the input and output data and where it belongs.

The next diagrams are an effort to flesh this out more. They are what this might look like with a relational tool but really even a document store like Mongo data structures would look similar.

First is the core data structures then a diagram of the core process to make it happen. (Blue Note: In this first diagram, the data in light blue is most of our Person Data - both to insure consistency across systems, but also as a potential central source of truth for person info - either via stored procedures or by maintaining a MongoDB store.) (Yellow Note: The data in Yellow is that “data driven” model for input and output so that as new sources and targets are added, we do not need to write new procedures.)

The entire process would be EVENT DRIVEN and could possibly be just one stored procedure that begins executing as new data arrives and finishes as that data is passed on to some other service as output from this service.

The following is a sequence of examples of how data would flow from TenStreet and a CONFIRMED status to Infinium then to Azure then to Cornerstone:

FROM TenStreet to Infinium (Get EmployeeID)

From Infinium Get EmployeeID to Azure Get Username

From Azure Get UserName to Cornerstone
